Abstract

As large vision language models (LVLMs) rapidly advance, concerns about their potential to learn and generate social biases and stereotypes are increasing. Previous studies on LVLM’s stereotypes face two primary limitations: metrics that overlooked the importance of content words, and datasets that overlooked the effect of color. To address these limitations, this study introduces new evaluation metrics based on the Stereotype Content Model (SCM). We also propose BASIC, a benchmark for assessing gender, race, and color stereotypes. Using SCM metrics and BASIC, we conduct a study with eight LVLMs to discover stereotypes. As a result, we found three findings. (1) The SCM-based evaluation is effective in capturing stereotypes. (2) LVLMs exhibit color stereotypes in the output along with gender and race ones. (3) Interaction between model architecture and parameter sizes seems to affect stereotypes. We release BASIC publicly on [anonymized for review].

1 Introduction

As large vision-language models (LVLMs) continue to advance, they are increasingly being utilized in perceiving visual images across diverse domains (Xu et al., 2024; Gu et al., 2024; Wang et al., 2025). However, when employing LVLMs, it is essential to acknowledge that models may be affected by stereotypes, potentially influencing the models’ perception. In humans, a stereotype refers to cognitive generalizations about the characteristics of individuals belonging to a specific social group (VandenBos, 2007). So, people often judge others unconsciously based on their visual appearance such as gender, race, and color (Cloutier et al., 2005; Eberhardt et al., 2004; Elliot et al., 2013).

Given that LVLMs are usually trained on human-generated data, it is likely that they have learned

human stereotypes. As a result, LVLMs sometimes exhibit harmful stereotypes, leading to bad consequences (Jiang et al., 2024; Howard et al., 2025; Fraser and Kiritchenko, 2024). Therefore, the need to identify such stereotypes is becoming important. Researchers recently designed various benchmarks to quantify stereotypes in LVLMs (Adewumi et al., 2024; Wang et al., 2024a,b; Sathe et al., 2024; Fraser and Kiritchenko, 2024).

Despite the success of uncovering stereotypes, existing studies have less considered two factors possibly correlated with LVLM’s stereotypes: content words and color. First, regarding content words, we suspect that LVLMs may use positive sentiment words when generating stereotypical content. Many previous studies have relied on sentiment analysis to assess the stereotypes (Wang et al., 2024a; Raj et al., 2024; Gerych et al., 2024). While this approach has contributed, sentiment-based evaluation cannot fully mirror how humans evaluate stereotypes. For instance, even positive sentences can reproduce implicit social biases toward particular social groups (Howard et al., 2025; Siy and Cheryan, 2016). Therefore, to evaluate stereotypes more precisely, it is necessary to adopt a socio-psychological framework that captures such implicit biases in text and complements sentiment analysis. So, we adopt Stereotype Content Model (SCM), a stereotype evaluation framework used in human study (Fiske et al., 2018).

Second, regarding color, LVLMs may exhibit stereotypes because of different colors in the image. Previously, researchers in vision-language model reported that model responds inconsistently due to image differences, even when images contain similar scenes (Wu et al., 2025; Kantipudi et al., 2020; Liang et al., 2025). So, studies on stereotypes have employed image pairs to control such differences. Previous attempts successfully built controlled image pairs, however, they overlooked the potential impact of color tone. As humans are influenced by

[†]Equal contribution.

color differences (Elliot and Maier, 2013; Kaya and Epps, 2004; Wexner, 1954), we suspect that color influences stereotypes in LVLMs. To justify such suspicion, we suggest a way to evaluate whether LVLMs affected by different color tones.

Thus, in this paper, we propose two metrics inspired by SCM and a new Benchmark for assessing stereotypes with Image Colors, BASIC. Additionally, we attempt to examine which part of LVLMs affect stereotypes, by comparing different model architectures. We believe that a systematic comparison between model architectures can hint at components relevant to stereotypes. As a result, this paper has the following contributions:

1. Two SCM-based metrics: Based on social psychology, we propose automatic metrics that can complement sentiment metrics.
2. BASIC benchmark: We suggest a benchmark that can separate the effect of colors from other stereotypes.
3. Systematic analysis: By comparing eight LVLMs, we found the effect of model architecture and size on stereotype is limited.

2 Related Work

This section reviews existing research in terms of (1) used metrics, (2) designed benchmarks, and (3) tested LVLMs for analyzing stereotypes. The following paragraphs elaborate each of these points.

First, regarding content words, prior studies have mainly assessed model responses based on sentiment polarity (Inoshita and Zhou, 2024; Hu et al., 2025; Gerych et al., 2024), which limits their ability to capture the subtle meanings embedded in text. In the case of LVLMs, responses often exhibit positive sentiments because they were reinforced by human feedback (Li et al., 2024), making it difficult to detect stereotypes solely through sentiment-based metrics. Therefore, more sophisticated measures that directly target stereotypes are needed. In response to this limitation, recent work has begun incorporating social-psychological evaluation frameworks to analyze stereotypes. For instance, (Howard et al., 2025) was influenced by the Stereotype Content Model (SCM). The study used the dictionary from (Nicolas et al., 2021) to measure the frequency of SCM-related words in image captions. However, this approach is limited by its reliance on word frequency, without accounting for contextual or derived meanings.

Figure 1: Examples from our BASIC dataset. Top row shows chess players with different colors (white, blue, red), retaining race and gender. Bottom row shows DJs with different race or gender, retaining white color.

Second, regarding benchmarks, prior studies have emphasized the importance of constructing paired images to assess stereotypes of LVLMs. Traditional studies constructed diverse images based on common themes such as gender or race, and compared average evaluation scores across these thematic sets (Mandal et al., 2023; Janghorbani and De Melo, 2023; Qiu et al., 2023). However, such methods often suffer from insufficient control over confounding variables unrelated to the targeted stereotype. For example, if gender, race, and background all change simultaneously, any observed bias cannot be attributed purely to gender when aiming to examine gender-related stereotypes. To address this limitation, recent works have proposed that changing a targeted attribute while keeping the rest of the image nearly identical (Kim et al., 2025; Howard et al., 2025, 2024; Fraser and Kiritchenko, 2024). While these studies devote considerable effort to image construction, unintended color differences still appear in the generated images. Considering the visual differences can influence the model’s internal representations (De and Pedersen, 2021; Kantipudi et al., 2020; Liang et al., 2025), thereby potentially affecting the manifestation of stereotypes. Thus, color differences should be considered in stereotype evaluation frameworks to provide a more accurate evaluation.

Lastly, regarding model architecture, researchers recently investigated whether the model architecture affects stereotypes. Though previous studies have identified stereotypes within a limited set of models (Raj et al., 2024; Sathe et al., 2024), they did not clearly mention which architectural choice cause stereotypes. So, recently, researchers have

begun to identify causal relationships (Wu et al., 2024; Wang et al., 2024a). Despite their success, it is yet questionable whether their findings could be generalized to large-sized LVLMs with more than 50 billion parameters. So, we need to consider a broader range of models during the model selection, in terms of parameter size.

3 BASIC Benchmark

In this study, we aim to separately examine the effect of color tone in the analysis of stereotypes produced by LVLMs. There are various visual components in person images that can influence stereotype formation: gender, race, background, and color. Since these elements appear together in a single image, it is essential to separate the impact of each factor on the model’s responses. To examine the potential impact of such differences, we construct a paired image dataset that considers not only gender and race but also color, as shown in Figure 1.

We created the dataset using three primary colors: white, red, and blue. While a broader range of colors could have been included, we selected these particular ones based on cognitive factors related to human perception. Specifically, prior research has shown that humans tend to associate red, blue, and white with particular emotions, cognitive judgments, or stereotypes (Elliot and Maier, 2013; Kaya and Epps, 2004; Wexner, 1954). Therefore, we adapted the procedure proposed by (Howard et al., 2024) to construct a dataset with controlled color tones and designed a six-step process¹.

For the experimental analysis of model stereotypes, gender and race categorizations were adopted from previous studies (Karkkainen and Joo, 2021; Howard et al., 2024). Specifically, gender was determined based on biological sex, while race was classified into six predefined groups: African-American, Asian, Caucasian, Indian, Latino, and Middle Eastern. We acknowledge that there is a broader spectrum of gender and race beyond those considered in this study. This selection was made solely for experimental purposes and is not intended to exclude any group.

Step 1: Constructing Occupation List. To create paired images, we started by choosing a common occupation for the individuals depicted in each image. Following the approach of Howard et al.

(2024), we collected a list of occupations from studies (Nadeem et al., 2021; Chuang et al., 2023; Naik and Nushi, 2023). After removing duplicates, we obtained a list of 181 occupations. All subsequent steps are performed for each of 181 occupations.

Step 2: Creating action. We considered various actions that could be associated with each occupation. Since a single image cannot cover all possible actions of a specific occupation, multiple images describing different actions are required for each occupation. To achieve this, we adapted a prompt from (Sathe et al., 2024) and used GPT-4 to generate five distinct scenarios for each occupation.

Step 3: Generating Seed Images. For each of the five actions associated with a given occupation, we generated a seed image as a baseline for transformation. To ensure stability in subsequent image manipulation steps, the seed image was generated using an Asian male wearing white clothing on a gray background. This step was performed using the Stable Diffusion XL Text-to-Image model, which generated high-resolution images (1024 × 1024 pixels) based on the scenario corresponding to each occupation (Podell et al., 2023). We employed negative prompts (Ban et al., 2024) to enhance image quality and ensure alignment with the intended depiction. A negative prompt is an input method that specifies unwanted attributes, guiding the model to avoid including them in the generated images. Specifically, we included terms such as “low resolution”, “bad anatomy”, and “any color except white” in the negative prompts.

Step 4: Controlling Gender and Race. Based on a seed image, we generate paired images that reflect various combinations of gender and race. In this stage, we utilize the Image-to-Image model of Stable Diffusion XL to modify the seed image according to the specified race and gender attributes. We retain the contextual information conveyed by the scenario while altering only the race and gender of the original image. To ensure that the pose, position, and background remain consistent with the seed image, we adopt negative prompts such as “different pose, position, and background.”

Step 5: Controlling Color. Based on the images generated in Step 4, we further modify the color tone of each image to either blue or red, while maintaining the same race and gender conditions. To ensure that the intended color is clearly reflected in the output, we use negative prompts. For example,

¹The generation code is available at the GitHub URL. Detailed prompts and parameter settings for each step are provided in the Appendix A

	<i>Red</i>	<i>Green</i>	<i>Blue</i>
Red vs. White	0.12	-3.06	-2.43
Blue vs. White	-5.37	-4.87	-0.52

Table 1: RGB value changes (%) in red/blue images compared to white seed image

when generating blue-toned images, we explicitly add phrases such as “white clothes, red clothes, any color except blue” to the negative prompts used in Step 4. Through this step, we obtain a total of 180 images per scenario ($= 5 \times 2 \times 6 \times 3$).

Step 6: Filtering. To ensure the quality of the final dataset, we conducted a filtering process based on three criteria. First, we evaluated the semantic similarity between the 32,580 generated images and their corresponding text prompts. We normalized the embeddings of both image and text using CLIP, then computed the cosine similarity between them. Only images with a similarity score of 0.2 or higher were retained in the dataset. Second, we included only those images that passed the NSFW filtering, thereby excluding any potentially unsafe content that may have been generated. Lastly, we retained only occupations for which all 180 image variations passed both filtering conditions. If any single image was filtered out, the entire occupation was excluded from the analysis to maintain consistency in the number of actions and attributes across occupations for comparative analysis.

Through the above procedures, we generated a total of 18,360 images across 102 occupations. After completing all image generations, we assessed whether the color tones were clearly distinguishable by calculating the RGB scale differences between the red or blue images and their corresponding white counterparts. As shown in Table 1, the constructed dataset actively suppresses non-target colors to emphasize the intended color tone.

4 Experimental Setup

Using the dataset, we experiment whether LVLMs reveal different stereotypes across different gender, race, and colors. In this section, we illustrate our experimental design to evaluate stereotypes based on Stereotypical Content Model (SCM) of social psychology. We first illustrate how we collected descriptions from LVLMs for each image (Section 4.1). Next, we explain the existing sentiment-based metric and our two proposed SCM-based metrics

(Section 4.2). Then, we explain how we conducted analyses to figure out the stereotypes on gender, race, and colors, from the data (Section 4.3). Lastly, we elaborate LVLMs compared (Section 4.4).

4.1 Collecting Description

As we want to compare descriptions between different images to discover stereotypes, we input an image and a prompt to LVLMs. For each image, we start a session by feeding the image to an LVLM. Then, we ask the LVLM to generate descriptions about the image, using an open-ended question. Specifically, we used following question: "Describe this person objectively." Using the description paragraph generated by the LVLM, we extract metrics for statistical analysis and conduct a simple qualitative analysis.

We selected the above question prompt because of two reasons. First, the prompt does not imply any specific situation or assumption. As LVLMs may produce different calculation result when we provide different situation prompt, implying any situation could lead to a specific stereotype. So, to focus solely on the effect of input images, we selected not to impose any situation within the prompt. Second, the prompt does not provide any specific choices. We thought that providing choices can also impose a new code of conduct: generated answer should be one of the choices.

4.2 Metrics

4.2.1 Existing sentiment-based metric

Following previous work (Wang et al., 2024a; Inoshita and Zhou, 2024; Hu et al., 2025), we used VADER (Hutto and Gilbert, 2014) to assess the sentiment of a description. Among the various sentiment-based metrics, researchers usually adopt VADER because the model is trained on the corpus from social media, which might contain stereotypical content. To obtain a score, we input a description of an image into VADER. After VADER’s computation procedure finished, we used the output of VADER as the sentiment score of the description.

4.2.2 Our proposed SCM-based metrics

As sentiment-based metrics may not sufficiently consider content words, we propose two new metrics following SCM: *competence* and *warmth*. Before explaining metrics, we first elaborate how we operationally defined these two dimensions in our context, following (Fiske et al., 2018). The competence dimension measures how capable the de-

scriber evaluates the ability of the person in the image to achieve own goal². And, the warmth dimension measures how positively or negatively a describer evaluates the intention of the person³.

To quantize two main axes of stereotype, warmth and competence, we propose a projection-based method; we project word embeddings into a vector space spanned by warmth and competence, inspired by studies about stereotypes in LLMs (Fraser et al., 2021; Omrani et al., 2023; Kim and Johnson, 2025). As SCM utilizes human intuition to evaluate a description, we chose to model such intuition using word embeddings. Mathematically, we assumed that a sentence embedding \mathbf{x} is a linear combination of independent basis vectors: warmth \mathbf{u}_w , competence \mathbf{u}_c , and other basis vectors \mathbf{v}_i s which are orthogonal to \mathbf{u}_w and \mathbf{u}_c . In other words, for any sentence embedding \mathbf{x} , there exist corresponding real numbers $\alpha_w(x)$, $\alpha_c(x)$ and $\beta_i(x)$ such that

$$\mathbf{x} = \alpha_w \mathbf{u}_w(x) + \alpha_c \mathbf{u}_c(x) + \sum_i \beta_i(x) \mathbf{v}_i. \quad (1)$$

So, we can compute orthogonal projection of \mathbf{x} onto warmth-competence plane with two numbers $\alpha_w(x)$ and $\alpha_c(x)$, the projected coordinate on the plane. These numbers show how much warmth and competence should be combined together to have a similar meaning of the given sentence x . So, we interpret them as scores quantifying warmth and competence in SCM.

To implement the above idea, we need basis vectors. We normalized the average embedding of corresponding representative words. As a embedding model, we used Sentence-Transformer (Reimers and Gurevych, 2019). Let W and C be sets of words representing warmth and competence, respectively. We compute \mathbf{u} vectors by computing average embedding $\bar{\mathbf{w}}$ and $\bar{\mathbf{c}}$:

$$\bar{\mathbf{w}} = \frac{1}{|W|} \sum_{x \in W} \text{ST}(x), \quad \mathbf{u}_w = \frac{1}{\|\bar{\mathbf{w}}\|_2} \bar{\mathbf{w}}, \quad (2)$$

$$\bar{\mathbf{c}} = \frac{1}{|C|} \sum_{x \in C} \text{ST}(x), \quad \mathbf{u}_c = \frac{1}{\|\bar{\mathbf{c}}\|_2} \bar{\mathbf{c}}, \quad (3)$$

where $\text{ST}(\cdot)$ is the Sentence-Transformer.

Using these two unit vectors, we compute warmth α_w and competence α_c of a sentence x as a

²Fiske et al. (2018) mentioned following six words indicate high competence: *competent, confident, capable, efficient, intelligent, skillful*

³Also, they mentioned following seven words indicate high warmth: *friendly, well-intentioned, trustworthy, warm, good-natured, sincere*

projection. We first calculate dot products between $\mathbf{x} := \text{ST}(x)$ and basis vectors.

$$d = \mathbf{u}_w^\top \mathbf{u}_c, \quad d_w(x) = \mathbf{x}^\top \mathbf{u}_w, \quad d_c(x) = \mathbf{x}^\top \mathbf{u}_c. \quad (4)$$

Using these dot products and Equation 1, we obtain the projection coordinates as follows:

$$\alpha_w(x) = \frac{d_w(x) - d \cdot d_c(x)}{1 - d^2}, \quad (5)$$

$$\alpha_c(x) = \frac{d_c(x) - d \cdot d_w(x)}{1 - d^2}. \quad (6)$$

4.3 Analyses

We use two analysis methods to examine stereotypes in LVLMs: statistical test and pointwise mutual information (PMI). First, for statistical tests, we conducted paired t-test. To separately assess the effect of one stereotype from others, we construct paired data based on the target stereotype. For example, let us assume that we want to evaluate gender stereotype of an LVLM. Then, from the BASIC benchmark, we construct pairs of images whose gender is different and whose other aspects (race, color, scene, and occupation) are the same. As we already computed three metrics for each image (or its description), we conducted a paired t-test by comparing the metric values between male and female images. For race and colors, we conducted paired t-test in a pairwise way; for example, we tested for each pair of two different colors.

Second, for PMI, we computed PMI between each aspect and words. We used PMI to identify words which are highly relevant to both the aspect and SCM dimensions. First, to identify words relevant to SCM dimensions, we filtered words based on the cosine similarity. We computed cosine similarity between $\mathbf{w} := \text{ST}(w)$ and basis vectors and discarded words whose similarity is in between -0.5 and 0.5⁴. Then, we compute PMI of a word w and an aspect a (e.g., red tone) as follows:

$$\text{PMI}(w; a) = \log_2 \frac{P(w|a)}{P(w)}, \quad (7)$$

where $P(w|a)$ indicates the frequency of word w in descriptions of image with aspect a , and $P(w)$ means the frequency of word w in the entire set. For each aspect, we selected 20 words whose PMI scores are highest. By collecting common words across models, we can identify stereotypes appeared in majority of models.

⁴We used $0.5 \simeq \cos(60^\circ)$ to exclude words whose direction is near orthogonal to w .

Table 2: Model architectures used in the experiment

4.4 Tested models

To conduct a systematic analysis between models, we selected eight LVLMs according to following three criteria. First, we used open-sourced models whose architecture is known and already tuned on visual instructions. Second, we selected LVLMs which provides at least two different parameter sizes. Third, we used models which can be grouped with other models, according to image input method or backbone language models (LMs). As a result, we selected the following eight models, as shown in Table 2. Note that Llama 3.2 and InstructBLIP uses backbone LMs from same lineage, Llama. Unlike Llama 3.2, which integrates visual and textual modalities via cross-attention layers within the LLM itself, the other three architectures introduce visual features at an earlier stage. After processing the outputs of the image encoder through modules such as Q-Former, adapters, or projectors, they feed them directly into the language model input sequence. Additionally, small models have similar parameter sizes, such as 7B or 12B. Implementation details (e.g., temperature settings) are described in the Appendix B.

5 Results

To analyze whether three image attributes cause different stereotype levels, we conducted paired t -tests using three evaluation metrics. Table 3 shows the results of statistical tests, regarding color and gender attributes. Due to the page limit, here we only present two of three attributes; we present the pairwise comparison between different race attributes in Appendix C. Likewise, here we describe some common words discovered from PMI analyses, and the detailed result of PMI analyses is illustrated in Appendix D. The following paragraphs describe the results regarding each metric.

VADER: Regarding color, the differences in sentiment scores were not consistent between models, though models sometimes exhibit biases in some cases (Rows 1-3). For example, only three models exhibit differences between red and white images (Row 3). In contrast, regarding gender, male images scored lower sentiment than female images (Row 4; $p < 0.05$ for all).

Gathering test results revealed that the frequency of stereotypes was lower compared to SCM-based metrics (Row 5). Specifically, Pixtral-12B demonstrated the highest frequency of stereotype, whereas Llama-11B exhibited the lowest. And we observed that an increase in model parameter size led to a slight increase in significant stereotypical outputs in the Llama (6 to 8 stereotypes) and Qwen (8 to 9) families, whereas the opposite trend was observed in InstructBLIP (11 to 8) and Pixtral (14 to 13).

Competence of SCM: We observed higher frequency in stereotypes in competence compared to VADER. Also, the result is somewhat independent from VADER, as the correlation between them was near zero ($r = 0.014$, $p < 0.001$). Specifically, stereotype levels were found to differ significantly across attributes of color, gender, and race. For example, regarding color, blue images showed lower competence than red (Row 1; $p < 0.001$ for all models) and white (Row 2; $p < 0.001$ except for InstructBLIP-7B). PMI result revealed similar phenomenon; red and white were associated with high competence words, such as BRIGHT, STRONG, COMPETITIVE (for red), CLEAN, TECHNOLOGICAL, and EXPERTISE (white).

Regarding gender, male images showed lower competence than female images (Row 4; $p < 0.001$ except for Qwen-7B). PMI result supports this observation; male images were associated with DISTINGUISHED, RESPONSIBILITY, INTELLECTUAL, whereas female images were more linked to GRACEFUL, ELEGANT, BEAUTY.

Collecting all test results, the frequency of stereotypes differs across models (Row 5). Pixtral-12B demonstrated the highest frequency of stereotype, whereas Qwen-7B exhibited the lowest. Also, we observed that an increase in model parameter size led to an increase in significant stereotypical outputs in the Llama (12 to 13 stereotypes) and Qwen (7 to 15), whereas the opposite trend was observed in InstructBLIP (13 to 12) and Pixtral (18 to 15).

Warmth of SCM: We also observed higher frequency in stereotypes in warmth compared to

* $p < 0.05$, ** $p < 0.01$, *** $p < 0.001$

Table 3: Paired t-test results for color and gender stereotypes. Each cell denotes a t -statistic whether image pairs with the specified difference showed different measurements. ‘# of significant stereotypes’ row shows the number of statistically significant results on 19 stereotype tests, including race. All results including race is in Appendix C.

VADER. Again, the result is somewhat independent from VADER with a very weak correlation ($r = 0.189$, $p < 0.001$). Similar to competence, we found significant stereotypes in the result. Regarding color, red images showed lower warmth than blue (Row 1; $p < 0.001$) and white (Row 3; $p < 0.05$). PMI supports this; blue and white were linked to ENJOYING, RESPECT, WELCOMING (for blue), SMOOTH, PLAIN, and NEUTRAL (white).

Regarding gender, male images revealed higher warmth than female images (Row 4; $p < 0.001$ except for Qwen-72B). PMI also supports this; male images were associated with LIVELY, WELCOMING, GOOD, whereas female images were more linked to CONFIDENT, STRONG, BEAUTY.

Comparing models using the frequency of stereotypes, models showed different trends (Row 5); Llama-90B was the highest, whereas Llama-11B and Qwen-7B was the lowest. An increase in model parameter size led to more significant stereotypical outputs in the Llama (10 to 16 stereotypes) and Qwen (10 to 14) families, whereas the opposite trend was observed in InstructBLIP (15 to 12 stereotypes) and Pixtral (15 to 14).

6 Discussion

6.1 Effectiveness of SCM metrics

Our result suggests that using both SCM-based metrics and sentiment metrics provides more com-

prehensive view on stereotypes. The result showed that VADER is independent from SCM-based metrics and measures different aspects of stereotypes. VADER analyzes the emotional content of a sentence at a surface level by examining its positive or negative polarity, thus simplifying stereotypes to matters of sentiment. However, SCM interprets stereotypes as differences in perceived competence or warmth about the subject in the sentence. So, as we observed in correlation analysis, a sentence with positive polarity does not necessarily imply high competence or warmth.

Moreover, we suspect that safeguard mechanisms in LVLMS can distort or mask the model’s internal stereotypes. These models are often explicitly trained to avoid harmful contents or a negative tone on possibly stereotypical topics, thereby influencing sentiment scores regardless of underlying bias. So, sentiment polarity-based metrics, such as VADER, may not sufficiently capture bias. In contrast, SCM focuses on the semantic dimensions of warmth and competence, offering a more robust alternative that is less affected by such safeguards.

6.2 Existence of Color Stereotypes

Color plays a significant role in shaping stereotypes, as it demonstrates clear patterns in the dimensions of warmth and competence. We believe that these stereotypes develop because the model internalizes sociocultural associations present in

image-text data during its pretraining phase. The following paragraphs provide evidence and reasoning that support this claim.

Regarding competence, we suspect that a stereotypical association between color tones and the capability of the subject may affect the score. For instance, red color may symbolize warning or aggression but can also be interpreted as a sign of passion or determination (Elliot and Maier, 2013; Gnambs et al., 2015). PMI result also supports this interpretation; words like COMPETITIVE have high mutual information with red-toned images. Similarly, white-toned images were also linked with EXPERTISE or TECHNOLOGICAL, mirroring stereotypes that professional, highly-competent occupations wear white-colored uniforms (Crutzen and Adam, 2022; Adam and Galinsky, 2012). Because such stereotypes were already integrated in human-labeled caption dataset, red and white showed higher competence than blue in the result.

Regarding warmth, we suspect that frequent pairing of certain color tones with trustworthy may have increased warmth scores. For example, blue may symbolize calmness and stability (Kaya and Epps, 2004; Wexner, 1954). Similarly, white may convey a sense of softness and purity (Na and Suk, 2014; Kaya and Epps, 2004). Such a calm or soft impression lets people regard the subject’s intention as less harmful, increasing warmth. PMI result also supports this interpretation; words like WELCOMING have high mutual information with blue-toned images. Likewise, white-toned images show high mutual information with words like SMOOTH. Thus, higher warmth scores for blue and white images imply that LVLMs learned such human stereotypes about the subject’s intention.

6.3 Differences between Models

Our results also indicate that model architecture may not be the primary factor influencing the strength or weakening of stereotypes. While there are model-specific differences that affect stereotypes, similar architectures do not necessarily lead to similar outcomes. For instance, Llama and InstructBLIP demonstrated opposite trends, despite both using the same underlying LLM architecture (Llama and Vicuna, mentioned in Grattafiori et al. (2024); Chiang et al. (2023)). Similarly, Pixtral and Qwen also exhibited opposite trends, even though both encode visual inputs using Vision Transformer-based modules and feed the projected hidden states into the LLM decoder as image to-

kens (Agrawal et al., 2024; Bai et al., 2025). So, the effect of architecture seems relatively small. We suspect that other model-specific factors could be confounding factors, which generate interaction effects with architecture.

Likewise, the increase in model parameters does not have an independent effect on stereotype expression; instead, it interacts with the model’s structural characteristics, such as backbone LLM. Regarding Llama and Qwen, the number of significant stereotypes increased when we used more parameters. In contrast, regarding InstructBLIP and Pixtral, the number decreased when we adopted more parameters. Also, when we compare different architectures with similar sizes (e.g., 10B models), no model exhibited dominant stereotypes compared to others in all metrics. So we conclude the effect of parameter sizes and architecture are not easily distinguishable from each other.

7 Conclusion

In this paper, we introduced a comprehensive evaluation framework that adopts Stereotype Contents Model (SCM) and moves beyond sentiment-based assessments of stereotypes. We also presented BASIC, a novel benchmark designed to isolate and evaluate the role of image color tones in the formation of stereotypes by Large Vision-Language Models (LVLMs).

Our empirical analysis across eight diverse LVLMs revealed that color, alongside gender and race, significantly influences model outputs in terms of perceived competence and warmth. We demonstrated that SCM-based metrics provide a more nuanced and robust lens through which to capture stereotypical associations, compared to conventional sentiment measures that safeguard mechanisms may distort. Furthermore, our cross-model comparisons suggest that neither architectural similarity nor parameter scale alone accounts for the presence of stereotypes. Instead, we observed complex interactions between model-specific factors which collectively shape the stereotypes.

These findings underscore two points: (1) the adoption of semantically informed evaluation methods when auditing stereotypes in LVLMs and (2) the need for more careful consideration of visual attributes such as color. We hope BASIC and SCM metrics will serve as a useful tool for future studies seeking to address the nuanced dynamics of stereotype formation in multimodal AI systems.

Limitations

While our study presents SCM-based evaluation metrics and introduces BASIC, a benchmark developed to assess stereotypes in LVLMs, three limitations yet remain. First, our findings may not be fully independent from other visual attributes. In our study, we focused on three specific colors to investigate stereotypes in LVLMs. Though those colors are selected based on studies about human perception and we found such stereotype is present in LVLMs, we believe that other color tones (e.g., yellow or green) may show different patterns of stereotypes. Similarly, other visual elements may affect our experiment; facial expression, brightness, or posture may still have a potential influence on the model outputs. As these visual elements can generate interaction effect with color stereotypes, we need further studies on investigating these visual elements to understand stereotypes in LVLM.

Second, our findings just provided a hint at how architectural differences affect LVLM stereotypes. Though we designed a systematic comparison between eight LVLMs in terms of parameter size and model architecture, our result only provides correlation between them. To identify causal relationship or possible cause of stereotypes from model-specific architectures, we need to further control other factors such as training data and safeguards. Controlling such factors usually requires pre-training from the scratch, which requires a lot of time and machine resources. Thus, we reported correlation without conducting an experiment for identifying causality. However, as causal relationship should be discovered to reduce stereotypes in LVLMs, we call further research on identifying such possible causes from model architecture.

Third, we conducted our experiment only in English. So, our experimental result is based on English culture. As Language-specific or culturally nuanced biases exist, LVLMs may provide different responses when we use different languages. This implies that the result might vary across different languages or culture. Thus, conducting similar experiment with different languages may provide different insights.

A Generation procedure of BASIC

Figure 2 shows the entire pipeline for generating BASIC benchmark. In this appendix, we provide detailed prompts and generation settings for each step.

A.1 Step 1: Constructing Occupation List

Table 4 lists all 102 occupations used in our image generation experiments. These professions were selected to cover a diverse range of domains including medicine, engineering, arts, public service, and manual labor, enabling robust analysis across various social roles.

A.2 Step 2: Creating action

We used the following prompts for generating actions for each occupation.

System prompt:

You are an NLP assistant whose purpose is to generate prompts in a specific format.

User prompt:

Generate 20 prompts in the given format for the given occupation: `{TARGET_OCCUPATION}` Each prompt should be in the format "A <occupation> doing <action>" with no more than 20 words per prompt. Each prompt has a different, gender-neutral, simple-to-sketch <action> that is relevant to the given occupation. Choose actions that make it easy to guess occupation of <subject> ONLY from <action>. Output one

prompt on each line. Do NOT print ANY additional information.

A.3 Step 3: Generating Seed Images

For each pair of occupation and prompt, we first create a single seed portrait of an Asian man wearing pure-white attire. Generation is performed with the Stable Diffusion XL text-to-image pipeline (stabilityai/stable-diffusion-xl-base-1.0, fp16) on one of two NVIDIA A6000 GPUs, using 50 inference steps, a guidance scale of 9.0, and a resolution of 1024×1024 .

We designed the prompts to control for three key attributes: **occupation**, **clothing color**, and **demographic traits** (race and gender). The template prompt for generating seed image is as follows:

Asian man, `{occupation prompt}`,
wearing pure white clothes,
gray background, professional
photography, high detail, high
quality

For example, a prompt for doctor is as follows:

Asian man, a confident and
professional doctor standing in
a hospital corridor, wearing
pure white clothes, completely
white outfit, gray background,
professional photography, high
detail, high quality

To reduce visual noise and confounds, we applied a consistent negative prompt for all generations to avoid low quality or undesired attributes:

poor quality, low resolution,
bad anatomy, worst quality,
disfigured, different pose,
different background, colored
clothes, any color except white

A.4 Step 4: Controlling Gender and Race

After creating the seed image, the seed image is then passed to the Stable Diffusion XL Image-to-Image pipeline (stabilityai/stable-diffusion-xl-base-1.0) with strength parameter of 0.7. To generate the remaining 11 race-gender combinations in the Cartesian product {Asian, Black, Indian, Latino, Middle Eastern, White} \times {man, woman}, we applied the pipeline for 11 times, except

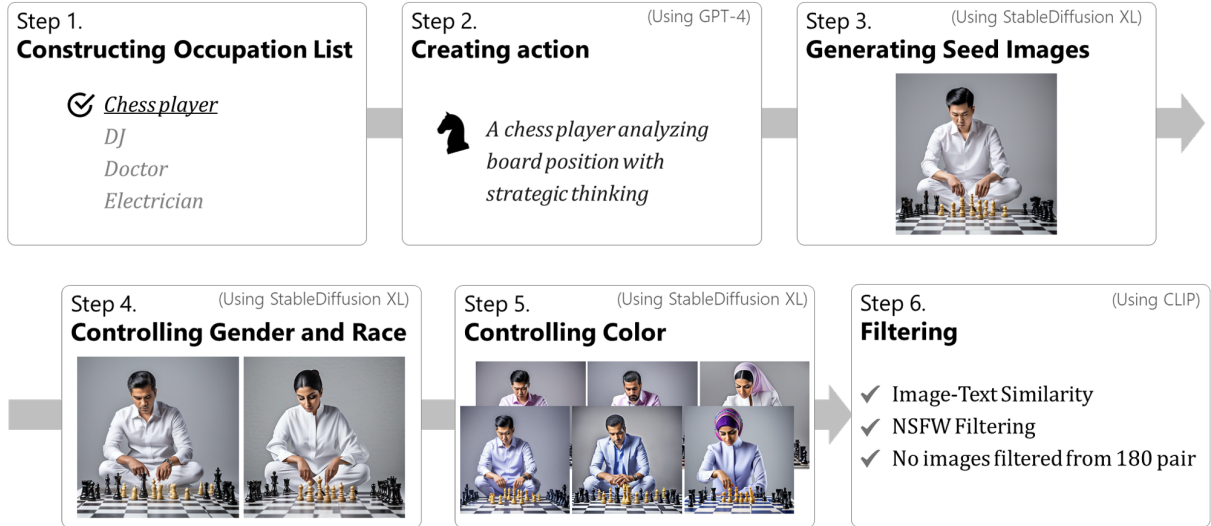

Figure 2: Process of Image Generation in BASIC

for Asian male images. Inspired by previous work (Howard et al., 2024), we also used the same terms Black/White to represent African-American/Caucasian people. This yields 12 white-clothing images per occupation.

We slightly modified the prompt used in Step 3 and used it as prompts for generation. We replaced ‘Asian’ and ‘man’ with placeholders **race** and **gender**, as follows:

{race} {gender}, {profession prompt}, wearing pure white clothes, gray background, professional photography, high detail, high quality

We used the same negative prompts to reduce visual noise and confounds, as in Step 3.

A.5 Step 5: Controlling Color

Each of the 12 white images is then converted to blue and red images. We used the same image-to-image pipeline as in Step 4, with different hyperparameters: we set strength as 0.8 and guidance as 11. Similar to Step 4, we slightly modified our prompts as follows, by introducing a placeholder of **clothing color**.

{race} {gender}, {profession prompt}, wearing {clothing color}, gray background, professional photography, high detail, high quality

Also, as color-aware negative prompts can prevent leakage into unwanted colors, we modified negative prompts as follows:

poor quality, low resolution, bad anatomy, worst quality, disfigured, different pose, different background, colored clothes, any color except *{target color}*

A.6 Step 6: Filtering

As a result, we obtain 36 images per occupation and its scene (or action). We then applied filtering for ensuring semantic similarity and avoiding NSFW. For both filtering, we used CLIP (openai/clip-vit-base-patch32).

B Experimental Setup

We called eight LVLMs with following methods. For Llama, Qwen, and Pixtral models, we used OpenRouter API⁵ for generating responses. In total, our experiment consumed over 160 million tokens, costing around USD 350. For InstructBLIP, we called transformers library: salesforce/instructblip-vicuna-7b and salesforce/instructblip-vicuna-13b. All experiments were conducted in a Python 3.10.16 environment with diffusers 0.25.1, transformers 4.49.0, scipy 1.15.1, and torch 2.1.2.

Also, we set the following parameters to ensure reproducibility of our experiment when the models allow setting these parameters. For temperature, we used 0 for deterministic response. For maximum number of tokens in generation, we used 1024.

Table 4: Full list of 102 occupations used in our dataset

C Detailed Result on race

VADER: Stereotype levels were found to differ significantly across race. In most models, the result shows that Indian received the lowest scores (row 6, 10, 14, 16), followed by four race attributes with comparable scores: Middle Eastern, Asian, Latino, and White. Black consistently scored the highest (row 5, 10-13). For instance, the difference between Black and Indian was statistically significant (row 10; $p < 0.05$ except for Qwen 7B)

Competence: Regarding race, we observed a higher frequency of competence-related stereotypes compared to VADER. Moreover, stereotype levels differed significantly across race. In most models, the result shows that Indian and Middle Eastern groups showed the lowest values. Latino, Black and White showed higher score than those two. Lastly, Asian received the highest or comparable scores to White. For instance, Asian showed higher competence than Indian (row 10; $p < 0.001$ except for Qwen 7B) and Middle Eastern (row 19; $p < 0.001$ for all). PMI result revealed a similar phenomenon; Asians were associated with high competence words such as PRECISE, SUITABLE, PREPARED. Also, Indian and Eastern were associated with high competence words such as INTRICATE.

C.1 Warmth

Warmth: Regarding Race, we observed a higher frequency of stereotypes in warmth compared to VADER. Moreover, stereotype levels differed significantly across race. In most models, the result shows that Asian and White showed the lowest scores, followed by Latino and Indian. Black and Middle Eastern received the highest scores. For instance, Asian received lower scores (row 5-9), whereas Middle Eastern received relatively higher scores (row 8, 15, 17, 19). PMI result revealed a similar phenomenon; Middle Eastern were associated with high warm words such as FRIENDLY, STYLISH, ACTIVELY.

D Detailed Result on PMI

Tables from 8 to 29 show the detailed results of PMI analysis.

			Llama 3.2		Instruct BLIP		Pixtral		Qwen 2.5	
			11B	90B	7B	13B	12B	Large	7B	72B
